

INTRODUCTION TO ACTUARIAL SCIENCE

3A DDEFI M2 AMSE M2 IMSA

Renaud Bourlès

INTRODUCTION (1)

- Specificity of insurance business: inverted production cycle Insurance contract = promise
 - \Rightarrow Importance of **forecast**
 - \Rightarrow Importance of **regulation**
- \triangleright Need to evaluate **ex-ante** and **precisely** the prices (and the risks). That is
 - ► To evaluate the (price of) **time** (actualization, link w/ finance)
 - ► To evaluate the **risks** (link w/ probability)

That is what **ACTUARIAL SCIENCE** does

INTRODUCTION (2)

Need to differentiate

\triangleright Life insurance

- \blacktriangleright insurance in case of life or in case of death
- ► long term
- ► less hazard

\triangleright Non-life insurance

- ► IARD (Incendie Accident et Risques Divers) in French
- ► short term
- ► high hazard

OUTLINE OF THE COURSE

\triangleright Life insurance model

- ► Mortality risk and pricing errors
- ► Main insurance products: fair premiums and prudent pricing
- ► Actuarial Present Value and Notations
- ► Exercises
- ▷ Non-life specificity
 - ► Provisioning
 - ► The variability of non-life risks
 - ► The role of financial markets

LIFE INSURANCE

- \vartriangleright Insurance in case of life; in case of death
- \triangleright Long term: pricing of time is important
 - ▶ value of $1 \in latter?$
 - ► actualization (NPV), what rate?
- \triangleright Random events
 - ► use of probability: "Actuarial Present Value"
 - \blacktriangleright what probability(ies)?
- \triangleright **Pricing** based on **forecasts** of:
 - ▶ interest rates
 - \blacktriangleright mortality rates

A SIMPLE EXAMPLE: ENDOWMENT POLICY

▷ Commitment: pay the policyholder $c \in in k$ years if she's alive ▷ in French: "capital différé en cas de vie"

▷ Assume an insurer selling n_a such contracts at a premium Π'' ▷ Its net profit at the end of the contract (in k years) will be:

$$R_{n_a} = n_a . \Pi'' . (1+i)^k - c . \mathcal{N}_V$$

where i is the interest rate and \mathcal{N}_V represent the # of policyholders alive at t = k (random at t = 0)

 \rhd assuming that all the policyholders have the same probability p to be alive at t=k

 \triangleright and that all these probabilities are independent, one has

$$\mathbb{E}(R_{n_a}) = n_a . \Pi'' . (1+i)^k - c . n_a . p$$

$$\sigma(R_{n_a}) = c . \sigma(R_{n_a}) = c . \sqrt{n_a . p . (1-p)}$$

▷ Numerical ex.: $n_a = 10,000; c = 100,000; t = 8; i = 6\%; p = 0.9865$ and $\Pi'' = 63,000$ give $\mathbb{E}(R_{n_a}) = 17,614,290$ $\sigma(R_{n_a}) = 1,154,030$

 \triangleright Remarks :

- ▶ small standard error; relatively "safe" contract for the insurer
- ► here Π["] fixed; in general, look for the premium s.t. E(R₁) = 0 labeled "actuarially fair premium" "fair": insurer's commitment = insured's commitment
- ► the difference between commercial and actuarial premium constitutes the **mathematical reserves** ("provisions mathématiques")

LIFE TABLES (1)

- \triangleright in previous ex., same survival proba p for all
- \triangleright in reality: use of **life tables**
- \triangleright that only depend on **age**
- \triangleright use of survival probabilities:

▶ if l_x = (# of ind. aged x at t = 0)
▶ and l_{x+k} = (# of ind. aged x at t = 0 alive at t = k)
▷ P(an ind. aged x at t = 0 is alive at en t = k) = \frac{l_{x+k}}{l_x}
▷ P(an ind. aged x at t = 0 dies before t = k) = 1 - \frac{l_{x+k}}{l_x} = \frac{l_x-l_{x+k}}{l_x}

▷ Ex.: $\mathbb{P}(\text{an ind. aged 35 dies before 45})=1-\frac{l_{45}}{l_{35}}$ $\mathbb{P}(\text{an ind. aged 35 dies between 40 and 45})=::::$

LIFE TABLES (2)

- ▷ Survival law of an ind aged x: l_x , l_{x+1} ,..., l_{x+k} ,..., l_w where w is the extreme age of life (≈ 110 y.o.)
- \triangleright Life table: survival law starting from $l_0 = 100,000$

French case: \exists several tables. Selection established by regulation

- ▷ TD & TV 88-90 (bylaw of April '93); observations by INSEE 1988-1990
 ▶ TD 88-90: on a pop. of males ; used for insurance in case of death
 ▶ TV 88-90: on a pop. of females ; used for insurance in case of live
 ▷ replaced by TH and TF 00-02; applicable since 2006 smoothed : age correction ← mortality spread between generation
- \triangleright HERE we will use TD and TV 88-90 (simpler)

MORTALITY RISK AND PRICING MISTAKES

- \triangleright Pricing (forecast) and
- \triangleright insurer's profit (realization), therefore high depend on:
 - ► assumptions on mortality (via tables)
 - \blacktriangleright and on interest rate(s)
- \triangleright Put another way, (life) a insurer faces:
 - ► mortality risk
 - ▶ pricing ("of time") mistakes
- Depending on the product (contract) characteristics
 these risks are more or less significant

THE MAIN (SIMPLE) PRODUCTS

For the main (simple) products, we will:

- ▷ Compute the fair premium, i.e. the Actuarial Present Value
- \triangleright Analyze how it depends on (mortality and i.r.) assumptions
- ▷ Define the **prudent pricing**
- \triangleright Compute the **variance** of the annual cost (for the insurer)

ENDOWMENT POLICY (IS BACK)

▷ Recall: pay $c \in$ in k years if alive ▷ Look for Π s.t. $\mathbb{E}(R_1) = 0$, i.e. $\Pi(1+i)^k - c.p = 0$ where n is the prob that the policyholder will be alive in k.

where p is the prob that the policyholder will be alive in k year

 \triangleright Defining $v \equiv \frac{1}{1+i}$ the actualization rate:

$$\Pi = \frac{c.p}{(1+i)^k} = c.v^k \cdot \frac{l_{x+k}}{l_x}$$

▷ This is the Actuarial Present Value of the product / contract

 $\triangleright \text{ Numerical ex.: } x = 40; \ k = 8; \ c = 100,000$ $\frac{\Pi \quad \text{TD 88-90 TV 88-90}}{i = 3.5\% \quad \dots \quad 74,917}$ $i = 7\% \quad 56,412 \quad 57,416$

▷ interest rate (8 years) more impacting than mortality risk ▷ most prudent pricing: i = 3.5% & TV (i.e. **regulatory** table)

 \triangleright Cost of the contract (for the insurer) from t = 0:

$$X_i = \begin{cases} c.v^k \text{ w/ probability } p = \frac{l_{x+k}}{l_x} \\ 0 \quad \text{w/ probability}(1-p) \end{cases}$$

$$\triangleright$$
 thus $\mathbb{E}(X_i) = \Pi$ and $\sigma(X_i) = c.v^k.\sqrt{\frac{l_{x+k}}{l_x}}\left(1 - \frac{l_{x+k}}{l_x}\right)$

- \rhd that is for n (identical and independent) contracts: $\mathbb{E}(X)=n.\Pi$ and $\sigma(X)=\sqrt{n}\sigma(X_i)$
- ▷ for 10,000 contracts and the prudent pricing above: $\mathbb{E}(X) = 749,170,000$ and $\sigma(X) = 100.\sigma(X_i) = 876.150$
- \triangleright We thus end up w/ a confidence interval at 95% for the total cost of the (n) contracts:

$$[X]_{95\%} = [747, 452, 746; 750, 887, 254]$$

 \triangleright Relatively small interval \rightarrow **few risk** for the insurer

(DEFERRED) TERM LIFE INSURANCE

- ▷ Commitment (at t = 0): pay $c \in$ to the beneficiary at the death of the insured IF it occurs between t = k and t = k + 1
- \triangleright In french "temporaire déc'es (différée)"

 \triangleright Warning: paid at death not at the end of the contract

 \triangleright **Assumption**: deceases are uniformly distributed over the year

▷ in expectation decease occurs at $k + \frac{1}{2}$ ▷ then at t = k + 1

$$\mathbb{E}(R_1) = \underbrace{\left(\Pi(1+i)^{k+\frac{1}{2}} - cq\right)}_{\text{en } t = k + \frac{1}{2}} . (1+i)^{\frac{1}{2}}$$

 \triangleright where q represent the proba of dying between t = k and t = k+1

 \triangleright The fair premium then writes

$$\mathbf{I} = \frac{c.\frac{l_{x+k} - l_{x+k+1}}{l_x}}{(1+i)^{k+\frac{1}{2}}}$$

 \triangleright Numerical ex.: $x=40,\,k=0$ (immediate), c=100,000

Γ

▷ small impact of the i.r. (immediate), huge mortality risk ▷ prudent pricing: i = 3.5% & TD (i.e. **regulatory** table)

$$ightarrow \sigma(X_i) = c.v^{\frac{1}{2}} \sqrt{\left(1 - \frac{l_{x+1}}{l_x}\right) \frac{l_{x+1}}{l_x}} = 5,239.7 \text{ (high)}$$

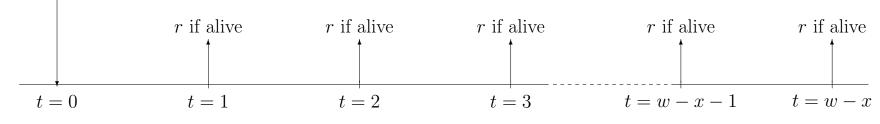

⇒ For 10,000 contracts (with prudent pricing) $[X]_{95\%} = [1,774,160;3,828,120]$ ⇒ big uncertainty!

LIFE ANNUITY (IN ARREARS)

- \rhd Engagement: pay $r {\ensuremath{\in}}$ at the end of each year (in arrears) as long as the insured is alive
- ⊳ in French: "rente viagàre (à terme échu)"

 \triangleright Fair premium:

 $\Pi = \dots$

▷ Numerical ex.: r = 10,000; x = 65 (retirement) $\frac{\Pi | TD 88-90 TV 88-90}{i = 3.5\% | 107,932 | 132,524}$ (amount to be paid at 65 to get 10,000€ a year until death) ▷ high impact of both interest rate and mortality rate! ▷ prudent pricing: i = 3,5% and TV

 \triangleright Cost of a policy:

$$X_{i} = \begin{cases} 0 & \text{with probability} \frac{l_{x} - l_{x+1}}{l_{x}} \\ \dots & \text{with probability} \dots \\ \dots & \text{with probability} \dots \\ \dots & \text{with probability} \dots \end{cases}$$

 \triangleright hence, using prudent pricing:

$$\mathbb{E}(X_i) = \Pi = 132,524 \text{ and } \sigma(X_i) = \sqrt{\mathbb{E}(X_i^2) - [\mathbb{E}(X_i)]^2} = 44,448.72$$

 \triangleright and for 10,000 policies

$$X]_{95\%} = [1, 316, 528, 050; 1, 333, 951, 950]$$

ACTUARIAL PRESENT VALUES AND NOTATIONS

 $\triangleright T_x \equiv$ random survival time of an individual aged x

$$\triangleright \mathbb{P}(T_x > k) = \frac{l_{x+k}}{l_x} \equiv {}_k p_x$$
$$\triangleright \mathbb{P}(k < T_x < k+k') = \frac{l_{x+k} - l_{x+k+k'}}{l_x} \equiv {}_{k|k'} q_x$$

▷ Actuarial Present Value of "pure" products $_{k|k'}^{APV_x}$ where k represents the deferred period and k' the duration

PURE PRODUCTS

▷ In case of life: Pure endowment $(1 \in \text{paid in } k \text{ year if the insured aged } x \text{ is still alive})$

$$_{k}E_{x} \equiv v^{k}.\frac{l_{x+k}}{l_{x}}$$

▷ In case of death: Deferred One Year Term (1 \in paid if the insured aged x dies between age x + k and x + k + 1)

$${}_{k|1}A_x \equiv v^{k+\frac{1}{2}} \cdot \frac{l_{x+k} - l_{x+k+1}}{l_x}$$

▷ Whole-life annuity ("rente viagère") ▶ in advance: $\ddot{a}_x = {}_0E_x + {}_1E_x + ... + {}_{w-x-1}E_x$ ▶ in arrears: $a_x = {}_1E_x + {}_2E_x + ... + {}_{w-x}E_x$

 \triangleright Whole-life term insurance ("Garantie décès vie entiére") \approx funeral contract ("contrat obsèques")

$$A_x = {}_{0|1}A_x + {}_{1|1}A_x + \ldots + {}_{k|1}A_x + \ldots + {}_{w-x-1|1}A_x$$

COMMUTATION FUNCTIONS

▷ To simplify the calculation: commutations functions
▷ ∃ tables of commutation functions: for given i.r. and life table
▷ Life commutation functions

$$D_x \equiv v^x l_x$$
 and $N_x \equiv D_x + D_{x+1} + \dots + D_w$

give

$$_{k}E_{x} = \frac{D_{x+k}}{D_{x}}, \quad \ddot{\mathbf{a}}_{x} = \frac{N_{x}}{D_{x}}, \quad \mathbf{a}_{x} = \frac{N_{x+1}}{D_{x}} \quad \text{and} \quad {}_{m|n}\ddot{\mathbf{a}}_{x} = \frac{N_{x+m} - N_{x+m+n}}{D_{x}}$$

 \triangleright Decease commutation functions

$$C_x \equiv v^{x+\frac{1}{2}} (l_x - l_{x+1})$$
 and $M_x \equiv C_x + C_{x+1} + \dots + C_{w-1}$

give

$$_{k|1}A_x = \frac{C_{x+k}}{D_x}, \quad A_x = \frac{M_x}{D_x} \quad \text{and} \quad _{m|n}A_x = \frac{M_{x+m} - M_{x+m+n}}{D_x}$$

EXERCISES

▷ A benefit C = 10,000 will be paid to a beneficiary in the event of death in the next 3 years of an individual who is simultaneously the owner and the insured, and who is today aged 50.

Price (with i = 3%) this policy (i) with a single premium and (ii) with constant annual premiums paid in advance during three years.

▷ A loan of $K = 10,000 \in$ is repaid with three constant annual payments of $4,000 \in$ (in arrears). An insurance contract guarantees, in the event of death of the borrower, the repayment of the remaining installment at the due term.

What is the Actuarial Present Value of this insurance at the time the loan is granted? Do the numerical exercise for an insured aged 40 with an interest rate of 3%.

Compute the fair constant annual premium to be paid in advance during the life of the loan.

EXTENSIONS

 \triangleright Benefit on the first death of (x) and (y)

$$1 - \frac{l_{x+k}}{l_x} \cdot \frac{l_{y+k}}{l_y}$$

 \triangleright Reversible (or joint) life annuity

$$\frac{l_{x+k}}{l_x} + \alpha. \left(1 - \frac{l_{x+k}}{l_x}\right) \cdot \frac{l_{y+k}}{l_y}$$

 \triangleright Varying annuities

- geometric progression $\left(\left(1+\rho\right)^k\right)$
- ▶ arithmetic progression (k + 1)

 \triangleright Variable interest rates

$$v_k = \frac{1}{1+i_1} \cdot \frac{1}{1+i_2} \cdot \cdot \cdot \frac{1}{1+i_k}$$

NON-LIFE INSURANCE (IARD)

- Differences with life insurance
- \triangleright Shorter term
- \triangleright More variability
 - But also
- \triangleright Claim settlement process (slower)
- \Rightarrow More complicated accounting (reserving)
- \Rightarrow Importance of **safety margin** (implicit/regulated in life insurance)
- \Rightarrow Importance of investment on the stock **market**

ACCOUNTING SPECIFICITIES

- ▷ Accounting tracks the **amount** of claims not the number!
- \Rightarrow Difficult to track the frequency and the average costs of claims
- \Rightarrow Profitability measured by the ratio C/P: (sum of) claims to (sum of) premiums ratio ("sinsitres sur prime")
- \triangleright Time for Claim settlement
- \Rightarrow differences between the accounting year and the **claim year**
 - ► Incurred But Not (yet) Reported **IBNR** claims
 - ► Reported But Not (yet) Settled **RBNS** claims
 - ► called "tardifs" in French
- \Rightarrow In France: three accounting statements
 - \blacktriangleright C1 reflects the accounting year
 - ► C10 and C11 reflects the occurrence year (resp. for "claims" and "premiums and profits")

RESERVING ("PROVISIONNEMENT")

- \triangleright To ultimately pay the IBNR (& RBNS) claims
- ▷ insurance companies have to set (claim) reserves ("PSAP: Provision pour Sinistres À Payer" in French)
- \triangleright i.e. to hold liquidity at year n
- \triangleright for claims (on contracts) from previous years
- ▷ the difference between reserves and the (real) costs of claims (from n k in n)
- ▷ determine a boni (or a mali) from claims reserving ("de liquidation de provisionnement" in French)

A SIMPLE EXAMPLE

- \rhd Consider next example where we want
- \triangleright to study the **changes in reserving** in the end of year n
- \triangleright to determine boni and mali

	n-4	n-3	n-2	n - 1	n	Total
Settlement at year n	1	2	10	177	294	484
+ Reserves on $12/31/n$	1	2	4	15	140	162
- Reserves on $01/01/n$		5	14	187		208
						438
= Costs of claims						
incurred in n					434	434
+ Costs of claims						
incurred before n	0	_1_	0	5		4
		boni		mali		

- \triangleright Claims reserving led to a **mali** of 4
- \triangleright because of **misevaluated** reserves/provisions for year n-1

EVALUATING CLAIM RESERVES: THE CHAIN-LADDER METHOD

- ▷ How to make (and update) forecast on outstanding claims (incl. IBNR & RBNS)?
- \triangleright Most popular method: Chain-Ladder
- \triangleright Assumption: \exists a regularity in the cadence of payments
- ▷ Use of incremental payments X_{i,j} *i.e.* the payments made in i + j for claims incurred in i
 ▷ and cumulative payments C_{i,j} = X_{i,0} + X_{i,1} + ... + X_{i,j}

 \triangleright The Chain-Ladder method assumes

$$C_{i,j+1} = \lambda_j \cdot C_{i,j}, \qquad \forall i, j$$

i.e. \exists a **recurrence relation** on cumulative payments

CUMULATIVE PAYMENTS AND RESERVING

 \rhd After t year, the amount remaining to be paid for claims of year i writes

$$R_{i,t} = C_{i,\infty} - C_{i,t}$$

 \triangleright And the **reserves** (provision) will correspond to the **forecast**

$$\widehat{R}_{i,t} = \mathbb{E}\left(R_{i,t} \mid \mathcal{F}_t\right) = \mathbb{E}\left(C_{i,\infty} \mid \mathcal{F}_t\right) - C_{i,t}$$

where \mathcal{F}_t represents the information available after t years $\mathcal{F}_t = \{(C_{i,j}, 0 \le i + j \le t\} = \{(X_{i,j}, 0 \le i + j \le t\}$ $\triangleright Remark : (\mathbb{E}(C_{i,\infty} | \mathcal{F}_t))_t \text{ is a martingale}$ \triangleright the Chain-Ladder method consist in estimating the λ_j s

 \triangleright on the basis of observations on n years (n - j obs for each j)

THE CHAIN-LADDER ESTIMATE

 \triangleright Chain-Ladder estimate: weighted **average ratio** on the n - j obs.

$$\widehat{\lambda}_{j} = \frac{\sum_{i=1}^{n-j-1} C_{i,j+1}}{\sum_{i=1}^{n-j-1} C_{i,j}}$$

$$\triangleright$$
 i.e. $\hat{\lambda}_j = \sum_{i=1}^{n-j-1} \omega_{i,j} \cdot \lambda_{i,j}$ with $\omega_{i,j} \equiv \frac{C_{i,j}}{\sum_{i=1}^{n-j-1} C_{i,j}}$ and $\lambda_{i,j} = \frac{C_{i,j+1}}{C_{i,j}}$

$$\triangleright Remark : \hat{\lambda}_j = \arg\min_{\lambda \in \mathbb{R}} \left\{ \sum_{i=1}^{n-j} C_{i,j} \cdot \left[\lambda - \frac{C_{i,j+1}}{C_{i,j}} \right]^2 \right\}$$

(can come from a weighted least-square linear reg. without cst of $C_{i,j+1}$ on $C_{i,j}$) \triangleright We can then estimate the cumulative payments

$$\widehat{C}_{i,j} = \left[\widehat{\lambda}_{n-i+1}...\widehat{\lambda}_{j-1}\right]C_{i,n-i+1}$$

 \triangleright and the claim reserves (assuming that all the claims have been settled after *n* year)

EXAMPLE (1)

$X_{i,j}$	0	1	2	3	4	5	$C_{i,j}$	0	1	2	3	4	5
1	3209	1163	39	17	7	21	1	3209	4372	4411	4428	4435	4456
2	3367	1292	37	24	10		2	3367	4659	4696	4720	4730	
3	3871	1474	53	22			3	3871	5345	5398	5420		
4	4239	1678	103				4	4239	5917	6020			
5	4929	1865					5	4929	6794				
6	5217						6	5217					

 \triangleright We then have

 $\widehat{\lambda}_0 = 1.38093$; $\widehat{\lambda}_1 = 1.01143$; $\widehat{\lambda}_2 = 1.00434$; $\widehat{\lambda}_3 = \dots$; $\widehat{\lambda}_4 = 1.00474$ \triangleright and we can complete the table

$C_{i,j}$	0	1	2	3	4	5
	3209	4372	4411	4428	4435	4456
2	3367	4659	4696	4720	4730	4752.4
3	3871	5345	5398	5420	5430.1	5455.8
4	4239	5917	6020	• • •	6057.4	6086.1
5	4929	6794	6871.7	6901.5	6914.3	6947.1
6	5217	7204.3	7286.7	7318.3	7331.9	7366.7

EXAMPLE (2)

- \triangleright Assuming that 5 years are enough to settle all the claims
- \triangleright the insurer has to set up reserves up to
 - \blacktriangleright 22.4 for year 2
 - \blacktriangleright 35.8 for year 3
 - \blacktriangleright 66.1 for year 4
 - \blacktriangleright ... for year 5
 - \blacktriangleright 2149.7 for year 6
- \triangleright That is a total of 2427.1
- The year after, we observe an additional diagonal,
 what changes the estimations and therefore the reserves
 creating boni and mali

EXTENSIONS

 \triangleright Probabilistic models (also use $Var(C_{i,j+1} | C_{i,j}))$

$$C_{i,j+1} = \lambda_j . C_{i,j} + \sigma_j . \sqrt{C_{i,j}} . \epsilon_{i,j}$$

with $\widehat{\sigma}_j^2 = \frac{1}{n-j-1} \sum_{i=1}^{n-j-1} \left(\frac{C_{i,j+1}}{C_{i,j}} - \widehat{\lambda}_j\right)^2 . C_{i,j}$

 \triangleright Econometric models (Poissonian regression)

- ► Assumptions
 - a year effect, and a delay effect
 - multiplicative effect

$$\blacktriangleright X_{i,j} \sim \mathcal{P}(A_i.B_j) \Rightarrow \mathbb{E}(X_{i,j}) = A_i.B_j$$
$$\widehat{Y} = \widehat{A} \cap \widehat{D}$$

$$\blacktriangleright X_{i,j} = A_i.B_j$$

▶ provides the same forecast as the Chain-Ladder estimate

FAIR PREMIUM AND NON-LIFE RISK

 \triangleright Contrary to a life insurance contract

 \triangleright several claims can occur on a single non-life contract

 \triangleright The cost of a policy (X) the depends on:

▶ the number of claims on this policy: N (random)

► the cost of each of these claims: Y_i , i = 1, ..., N (random) with $X = Y_1 + ... + Y_N$

 \triangleright the **fair premium** will then be:

 $\Pi = \mathbb{E}(X) = \mathbb{E}_N[\mathbb{E}(X \mid N)] = \mathbb{E}_N[\mathbb{E}(Y_1 + \ldots + Y_N \mid N)]$

 \triangleright Then, if

► the Y_{ij} s (the costs of the j^{th} claim of individual i) are i.i.d. knowing N_i (the # of claims of ind. i)

► the N_i s are i.i.d. $\mathbb{E}(X) = \mathbb{E}_N[\mathbb{E}(N.Y)] = \mathbb{E}(N).\mathbb{E}(Y)$

VARIABILITY OF A NON-LIFE RISK

 \vartriangleright Similarly, the variance of this cost depends on both

- ► the variability in the number of claims per contract
- ► the variability in the cost of a claim

 \triangleright Under the above assumptions:

$$\begin{split} \mathbb{E}(X^2) &= \mathbb{E}_N[\mathbb{E}(X^2 \mid N)] = \mathbb{E}_N[\mathbb{E}((Y_1 + \ldots + Y_N)^2 \mid N)] \\ &= \mathbb{E}_N\left[\mathbb{E}\left(\sum_{i=1}^N Y_i^2 \mid N\right) + \sum_{i=1}^N \sum_{j \neq i} \mathbb{E}(Y_i Y_j \mid N)\right] \\ &= \mathbb{E}_N\left[N.\mathbb{E}(Y^2) + N.(N-1)\mathbb{E}(Y)\mathbb{E}(Y)\right] = \mathbb{E}(N).\operatorname{Var}(Y) + \mathbb{E}(N^2).\left[\mathbb{E}(Y)\right]^2 \\ &\text{and} \\ \operatorname{Var}(X) &= \mathbb{E}(N).\operatorname{Var}(Y) + \mathbb{E}(N^2).\left[\mathbb{E}(Y)\right]^2 - \left[\mathbb{E}(N).\mathbb{E}(Y)\right]^2 \\ &= \left[\mathbb{E}(Y)\right]^2.\operatorname{Var}(N) + \mathbb{E}(N).\operatorname{Var}(Y) \end{split}$$

 \triangleright And in the **particular case** where $Var(N) = \mathbb{E}(N)$ (for ex. if $N \sim \mathcal{P}$) $Var(X) = \mathbb{E}(N).\mathbb{E}(Y^2)$

EXAMPLE

Consider a portfolio of 400,000 identical contracts for which

 \triangleright the number of claims per contract can be approximated by a $\mathcal{P}(0.07)$

- ▷ the claims lower than $M = 200,000 \in$ have an expectation $C_1 = 10,540 \in$ and a standard error $\sigma_1 = 19,000 \in$
- ▷ a proportion p = 1% of claims are higher than M (for clipping purpose, "écrétage"). The expectation of these big claims is $C_2 = 410,000 \in$ and their standard error $\sigma_2 = 1.3 \text{ M} \in$
- ▷ the number of claims per contract are assumed to be i.i.d., and given these numbers, the size of claims are also assumed to be i.i.d.
 - ► Compute the annual fair premium (on a contract)
 - ▶ Compute the standard error of the cost of a contract
 - ► The insurer evaluates its charges to 15% of the commercial premium Π["]. Compute the value of Π["] that makes lower than 10% the prob that the insurer looses – on its entire portfolio – exceed 20 M€

LINK WITH THE REGULATION

- ▷ the Value at risk at $1 \alpha\%$ (V@R_{1- α}): the potential loss than can occur on a portfolio with a proba α
- ▷ Quantile of level α of the distrib of profits and losses X: $\mathbb{P}(X > V@R_{1-\alpha}) = \alpha$
- \triangleright Solvency 2 : the Solvency Capital Requirement (SCR)
 - \blacktriangleright target level of own funds the insurance company should aim for
 - ► corresponds to a Value at risk at 99.5% over one year
 - ► capital that enables the insurer to absorb bicentennial (adverse) events

NON-LIFE INSURANCE AND FINANCIAL MARKETS

- \vartriangleright In life insurance: use of risk-free interest rate i
- In non-life, no assumption on the investment of premiums income nor on the investment of reserves
- \triangleright whereas, it has an direct impact on insurer's profit
- \triangleright Even in the case of a decrease in loss ratio,
- ▷ the financial equilibrium can be threatened by "bad" investments that is a degradation of assets
- \triangleright Case study: the evolution of car insurance price (by Gilbert THIRY, Consultant)

CASE STUDY - CALCULATION ASSUMPTIONS (1)

▷ Financial equilibrium obtained for a claims-to-premiums ratio C/P=78%
 ▷ Technical result

AssetLiabilityPremiums: 100Claims: 78Financial products: 7Overhead costs: 29

 \triangleright After one year

- ► Annual claims frequency: -6%
- ► Average cost: +2%
- \Rightarrow Cost of claims: -4% (0.94x1.02=0.96)
- \blacktriangleright Financial products: -10%
- ► Overhead costs: +2%

CASE STUDY – CALCULATION ASSUMPTIONS (2)

 \triangleright The same technical result can then be obtained

 \triangleright by decreasing premiums by 1.8%

AssetLiabilityPremiums: ...Claims: 74.9Financial products: 6.3Overhead costs: 29.6

 \triangleright **Issue**: the fall of financial markets also led to

- \triangleright a loss on the **investment of reserves**
- \triangleright that represent 1.2 times the annual premiums
- \triangleright For the average structure of investment by insurance companies

 \triangleright a fall of 30% on the shares portfolio gives:

	y-1	y
Bonds	66	66
Shares	25	17.5
Real estate and other investments	9	9
Total	100	92.5

CASE STUDY – INCREASE IN PREMIUMS

 \triangleright To reconstruct reserves

▷ the insurance companies should then increase premiums by: $7.5\% \ge 1.2 = 9\%$

▷ This increase is mitigated by good technical results ▷ so to avoid losses,

 \triangleright premiums has to increase by

 $1.09 \ge (1 - 0.982) = 1.07$ that is 7%

$CASE \ STUDY - EXERCISE$

 \triangleright This result is obviously impacted by the portfolio structure

 \triangleright Under the same assumptions, the increase in premiums needed for two companies

	Company A	Company B
Bonds	51	81
Shares	40	10
Real estate and others	9	9

 \triangleright will be highly impacted by the proportion of shares in the investment
